Abstract

19

20

21

22

- Despite important advances in network ecology, the link between the structure of an interaction network and management or conservation is still tenuous. Perhaps in part because of a lack of theoretical framework, efforts to strengthen this link have been mainly focused on whole-network properties instead of underlying mechanisms.
- 2. Here, we leverage recent advances in control theory to develop an approach to assess the "manageability" of ecological networks. We then illustrate its application using ten pairs of uninvaded
 and invaded plant-pollinator communities. We also characterise species' suitability for inclusion in
 management interventions by exploring the entire space of alternative control strategies. Specifically,
 we measure the extent to which species (i) are necessary to steer the state of the community and
 (ii) are able to affect the abundance of other species.
 - 3. We found that the networks' manageability is most strongly determined by the ratio of plant to pollinator richness, which in turn constrains the networks' degree distribution. We also found that invasive plants have a dominant position in every invaded community and that this dominance is underpinned by high asymmetries in the dependences of their interaction partners.
- 4. Synthesis. Our results provide novel insight into the design of ecologically-informed management interventions and lay the foundation for further work on the control of ecological networks.
- 25 Keywords: Driver species, ecological networks, management interventions, mutualism, network control
- theory, plant population and community dynamics, species importance

Introduction

In a complex system, the whole is often greater than the sum of its parts (Montoya, Pimm & Sole 2006). Within community ecology, a complex-systems approach has led to the development of analytical and simulation tools with which to understand, for example, the role of species embedded in a network of interactions (Bascompte & Stouffer 2009; Stouffer et al. 2012). The inherent complexity of nature, however, has regularly hindered—or at least complicated—our ability to find management solutions to many problems ecological communities face. To overcome this obstacle, we require a framework that 32 allows us to explain, predict, and manage ecological communities, particularly when they are confronted with perturbations (Green et al. 2005). Ideally, such a framework is equipped to account for their complex structure and the dynamics that determine the species abundances and the state of the community. Among the various possibilities, control theory appears to be a strong candidate (Isbell & Loreau 2013). Widely used in engineering to determine and supervise the behaviour of dynamical systems (Motter 2015), it is well equipped to deal with the many feedbacks present in ecological communities (Liu & Barabási 2016). Research in this area has established a strong link between the structure of complex networks and their controllability—the relative ability to manipulate network components to drive the system to a desired state (Liu, Slotine & Barabási 2011; Cornelius, Kath & Motter 2013; Ruths & Ruths 2014). These advances suggest that it is in principle possible to alter a whole ecological community's composition by modifying the abundances of only a few species. Applications of control theory to ecological networks can also take into account the extent to which changes in the abundances of one species may ripple through the community (Cornelius et al. 2013). Therefore, control theory could also be harnessed to help identify which species are most relevant from a structural and dynamic perspective. This information is valuable not only for basic ecology, but it might be also relevant to address more applied management and conservation challenges. This is particularly true in the context of biotic invasions, where identifying key players in the community is a prerequisite to informed attempts to alter the state of invaded ecosystems and maintain the state of uninvaded ones. Despite recent advances in network theory, practical challenges to the conservation of interaction networks persist (Tylianakis et al. 2010), and the link between the structure of complex networks and our ability to manage and conserve them is still ambiguous (Blüthgen 2010; Kaiser-Bunbury & Blüthgen 2015). To complicate things further, biotic 53 invasions can induce dramatic changes in the patterns of interactions that determine the structure of ecological networks (Tylianakis et al. 2008; Ehrenfeld 2010), in particular pollination (Olesen, Eskildsen & 55 Venkatasamy 2002; Aizen, Morales & Morales 2008; Bartomeus, Vilà & Santamaría 2008; Vilà et al. 2009; Traveset et al. 2013). Understanding how the differences in network structure before and after invasion 57 impact our ability to manage the communities is thus a double challenge, but it is also the critical first step towards a fully informed recovery. Despite the apparent overlap, the control-theoretic perspective

- 60 has not been adopted in an invasion context.
- To bridge this gap, we outline an approach to apply control theory in an ecological context and implement
- 62 it using empirical data. Specifically, we use a set of ten pairs of uninvaded and invaded plant-pollinator
- 63 communities to investigate the link between invasion, network structure and ecological management.
- While doing so, we focus on two particular questions. First, grounded in the difficulties usually involved
- 65 with invasive-species eradication and ecosystem restoration (Woodford et al. 2016), we ask whether
- invaded networks have lower levels of "manageability" than their uninvaded counterparts; that is, whether
- they require a greater proportion of species to be managed to achieve the same level of control. Second,
- 68 we ask whether some species are more important than others at driving the population dynamics of the
- 69 community and which factors determine this importance.

Theoretical framework

- At the core of representing ecological communities as complex systems sits the idea that the state of
- ₇₁ any given node depends on its state, the state of the nodes it interacts with, the state of the nodes they
- ₇₂ interact with, and so on. These dependencies are given by the structure of the interactions, the dynamic
- relationships between nodes, and the mechanisms of self-regulation. This representation has been very
- 74 useful for our understanding of ecological communities and might be advantageous for a more formal
- $_{75}$ $\,$ approach to ecological management based on control theory.
- The overall objective of control theory is to be able to steer a system from one state to another in finite
- time. However, in complex systems like ecological communities, the large number of nodes and interactions
- as well as their non-linear dynamics render its control extremely challenging. On one theoretical extreme,
- ⁷⁹ for instance, any ecological community could be fully controlled if we control the state of every species
- 80 independently. On another, the mechanisms of self-regulation and the multiple feedback cycles found
- in ecological communities mean it is also theoretically possible to control the whole community by
- directly modifying the state of just a single species (Rahmani et al. 2009; Cowan et al. 2012). Although
- mathematically correct, neither of these options are practical in real-world applications: the first because
- 84 it is infeasible to design and implement interventions that modify the abundance of every single species
- 85 in a community, and the second because the control signal might require unreasonably large amounts of
- time, energy, or unattainable rapid changes on the state (Yan et al. 2012; Motter 2015). Here we explore
- an intermediate point between these two trivial solutions.
- 88 In particular, we leverage the principle of species interdependence to find an intermediate set of driver
- 89 nodes to control the network (Liu & Barabási 2016). When we focus on net interspecific effects, it is

possible to identify a minimum number of nodes the control of which can theoretically drive the state of every other node in the network to a desired configuration. Conveniently the information necessary to determine this minimum number of driver nodes D is fully contained in the network structure (Kalman 1963; Liu et al. 2011; Motter 2015). Such a system can be described by $\frac{dx}{dt} = \mathbf{A}x + \mathbf{B}u(t)$, where the change of its state over time $(\frac{dx}{dt})$ depends on its current state x (for example, the species' abundances), an external time-varying input u(t) (the control signal), and two matrices A and B, which encode information 95 about the network structure and how the species respond to the external input, respectively. If S is the number of species in the community, the matrix **A** has size $S \times S$ whereas the matrix **B** has size $S \times D$. 97 The goal of structural controllability, which we employ here, is to use the information contained in A to generate a supportable estimate of **B** (and by extension D). This focus allows us to gain insight of the inherent controllability of a network, and the roles of the species that compose it, without being 100 overly dependent on the particular choices of how the system dynamics are modelled or characterised. 101 The trade-off of our approach is that, because of the assumption of linearity, structural controllability 102 alone does not allow us to fully design the time-varying control signal u(t) that can drive the system 103 from one particular equilibrium to another. Nevertheless, the lessons gained when assuming linearity—at 104 both the network and the species level—are a prerequisite for eventually understanding nonlinear control 105 (Liu et al. 2011; Liu & Barabási 2016).

Manageability

120

The number of driver nodes D provides a structural indication of how difficult a network's control might 107 be. This is because systems that require a large number of external input signals are intuitively more 108 difficult or costly to control. In an ecological context, external inputs that modify the state of a node can be thought of as management interventions. Therefore, the density of driver nodes $n_D = \frac{D}{S}$, where S is the total number of species in the community, is a measure of the extent to which network structure 111 can be harnessed for network control. For instance, a hypothetical "network" in which species do not 112 interact would require direct interventions for every single species to achieve full control, whereas a linear 113 food chain would require just one species to be directly controlled to harness cascading effects through 114 its trophic levels. From this perspective, it is possible to use n_D as an index of the manageability of an 115 ecological community, understood in the context of how difficult is to modify the abundances of species in 116 the community using external interventions—a common theme in ecosystem management, conservation, 117 and restoration. It has been recently shown that calculating D is equivalent to finding a maximum matching in the network

(Liu et al. 2011). In a directed network, a matching consists of a subset of links in which no two of them

share a common starting or ending node (Figure 1, Supporting Information S1). A given matching has

maximal cardinality if the number of matched links (also referred to as the matching size) is the largest possible. A maximal cardinality matching is then called a maximum matching if the sum of the weights of the matched links (also referred to as matching weight) is again the largest possible (West 2001).

Once we have the subset of links that constitute a matching, we can also classify the nodes in the network based on that matching (Figure 1). A node is called *matched* if it is at the end of a matched link and unmatched otherwise. A node is also called superior if it is at the start of a matched link. Note that a node cannot be superior if it has no outgoing links. Notably, these node categories are what helps us to link a maximum matching back to the concept of network controllability, as follows. Unmatched nodes are the driver nodes D because they have no superior in the network and must be directly controlled by an external input (Liu et al. 2011). Each matched node, on the other hand, can be controlled by its superior.

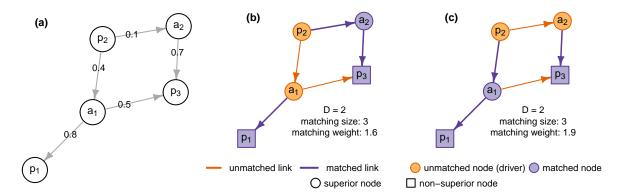

Figure 1: **Matchings of a simple network**. (a) We start with a network in which the direction of the links indicates the potential direction of control; for example a link from a_I to p_I indicates that the state of p_I is influenced by the state of a_I . The numbers indicate the weight of each link. (b & c) This network has two maximal cardinality matchings; that is, two configurations in which it would be possible to exert full control of the network via external input signals to a minimal set of nodes. In both cases, the three matched links (purple arrows) represent the control paths through the network and provide an indication of the matched nodes (purple), which are controlled by superior nodes within the network (circular nodes). Unmatched nodes (orange) are called driver nodes because full network control requires external signals to be applied to them. Out of the two maximal cardinality matchings only one (c) has maximum weight and therefore is also a maximum matching. Further examples can be found in Supporting Information S1.

Note that this framework requires a directed network in which the direction of the links corresponds to
the direction of control. In the "Methods" section below, we explain our approach to determining the link
direction in pollination networks.

Relative importance

While calculating n_D measures the manageability of an ecological community, it does not provide information about the identity of the species that compose the set of driver nodes. Ecologically, potential differences between species are relevant because management and conservation resources are limited, and therefore ecological interventions should be focused on the set of species that might provide the largest impact. Moreover, maximum matchings in a network are often not unique, and each maximum matching

indicates unique paths that can potentially be used to control the network. We harness this property and 140 use a network's complete set of maximum matchings to characterise each species' relative importance in driving the state of the community. One possibility is to characterise a species by the frequency f_D with 142 which it is classified as a driver node within this set of matchings. However, the profile of our networks indicates that a large proportion of species were classified as driver nodes because of external interventions required to achieve full controllability and not because they influence the abundance of other species 145 (Supporting Information S2). Furthermore, the precise role of driver nodes is more ambiguous when full 146 control is unfeasible or undesired—often the case in ecological settings. We therefore also calculate the 147 frequency f_S with which a species is classified as a superior node since this is the frequency with which 148 they form part of possible control paths. 149 Most commonly, structural controllability assumes unweighted networks—links exist or not, and hence 150 f_D and f_S can be calculated by computing all possible maximum-cardinality matchings. However, we 151 take the link weights into account when calculating the matchings here because the weights can reveal significant ecological patterns and processes that might be undetectable in unweighted networks (Scotti, Podani & Jordán 2007; Tylianakis, Tscharntke & Lewis 2007; Vázquez et al. 2007; Kaiser-Bunbury et al. 154 2010). Additionally, species A may interact with both species B and C but depends strongly on B and 155 only weakly on C. Intuitively, a management intervention designed to indirectly modify the abundance 156 of species A is more likely to succeed if the abundance of B, rather than C, is directly controlled. A 157 complication of including the interaction weight when calculating the maximum matching, however, is 158 that empirical interaction strengths are to some extent stochastic and depend on proximate factors such 159 as sampling method and intensity (Gibson et al. 2011). We overcome this issue by calculating all maximal 160 cardinality matchings and then ranking them by their matching weight. By following this approach, we effectively give priority to the species that participate in the pathways that potentially have the largest

Methods

restrictions (Jordano 2016).

We next applied the previously defined framework to ten paired pollination networks. Each network pair was composed of a community invaded by a plant and a community "free" of the invasive species. Four pairs were obtained from natural or semi-natural vegetation communities in the city of Bristol, UK (Lopezaraiza-Mikel et al. 2007). These networks are comprised of 19–87 species (mean 55), and non-invaded plots were obtained by experimentally removing all the flowers of the invasive species Impatients grandulifera. The other six pairs were obtained from lower diversity Mediterranean shrublands

impact on the community while acknowledging the limitations associated with sampling and its potential

in Cap de Creus National Park, Spain (Bartomeus et al. 2008). These networks are comprised of 30–57 species (mean 38); in contrast to the above, uninvaded communities were obtained from plots that had not yet been colonised by either of the invasive species Carpobrotus affine acinaciformis or Opuntia stricta.

Further details about the empirical networks can be found in Supporting Information S3.

We then specified the structure of all networks using pollinator visitation frequency, which has been 175 shown to be an appropriate surrogate for interspecific effects in pollination networks (Vázquez, Morris 176 & Jordano 2005; Bascompte, Jordano & Olesen 2006). To further examine whether this decision would 177 influence our results, we also evaluated the effect of using pollinator efficiency or pollinator importance as 178 alternative measures in a different data set that lacked invasive species (Ne'Eman et al. 2010; Ballantyne, 179 Baldock & Willmer 2015), and we found quantitatively similar results for all three options (Supporting 180 Information S4). Because our approach depends on the network topology, we also evaluated the robustness 181 of our results to the undersampling of interactions. Specifically, we calculated n_D and species relative 182 importance for 500 random subsamples of each empirical network in which the weakest links were more likely to be removed. Our sensitivity analysis indicated that, even in the absence of complete sampling, a control-theoretic approach can still be applied (Supporting Information S5). 185

Manageability

We began by quantifying the manageability of each network. To do so, we calculated the networks' maximum matching and determined the minimum proportion of species n_D that need external input signals to fully control the species abundances in the community. Note that because all maximum matchings have the same matching size, it is only necessary to calculate one of them. To simplify the analysis, if a network had more than one component (two species are in different components if there exists no path between them and are hence independent of each other in terms of network control) we only considered the largest. Smaller components were present in eleven out of the twenty networks and were typically composed of just one plant and one pollinator. Their removal represented an average loss of 4.7% of the species and 2.7% of the interactions.

Weighting & directing links

As we noted earlier, the maximum-matching approach requires a directed network in which a link from species i to species j indicates that the abundance of j can be affected by the abundance of i. This implies that we need first to identify a directionality for the links between species that is consistent with the dynamics of the community (Figure 2). In some ecological networks, establishing the directionality can appear relatively straightforward, for example when links represent biomass transfer or energy flow (Isbell

Loreau 2013). Interspecific effects in pollination networks, however, are not strictly directed since the
benefit is mutual between interacting species. Nevertheless, the relative extent to which a given pair
of interacting species affect each other can be quantified by the magnitude of the mutual dependence
between them (Bascompte et al. 2006). The dependence of plant i on pollinator j, d_{ij} , is the proportion
of the visits from pollinator j compared to all pollinator visits to plant i. Likewise, the dependence of
pollinator j on plant i, d_{ji} , is the proportion of the visits by pollinator j to plant i compared to all visits
of pollinator j. Using dependences generates a weighted bipartite network in which all interacting pairs
are connected by two directed links (Figure 2b).

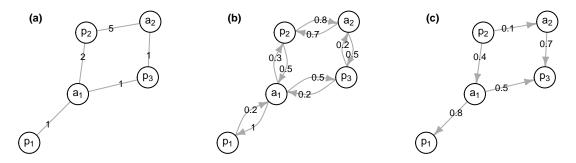

Figure 2: Different ways to depict quantitative mutualistic networks. (a) Pollination networks are frequently described by the observed number of visits between each plant and animal species. (b) Based on that visitation data, the mutual dependences between interacting species are calculated directly based on the relative visitation frequencies. (c) The relative differences of these dependences—the interaction asymmetry—then provide a means to estimate the dominant direction of the interspecific effects.

Given the respective dependences, the extent to which species i affects species j relative to the extent to which j affects i can be summarised by the interaction asymmetry (Bascompte et al. 2006) given by

$$a(i,j) = a(j,i) = \frac{|d_{ij} - d_{ji}|}{\max(d_{ij}, d_{ji})}.$$

Previous research has shown that mutual dependences are often highly asymmetric in natural communities (Bascompte et al. 2006); in other words, if a plant species is largely dependent on a pollinator species, then that pollinator tends to depend rather weakly on the plant (or vice versa). We therefore simplified 212 the network so that interacting species are connected by only one directed link when mutual dependences 213 are asymmetric (Figure 2c). This simplification, while maintaining ecological realism, is advantageous 214 for several reasons. First, it is consistent with previous advances in structural controllability; second, it 215 prevents the singular case in which the network could be perfectly matched rendering D=1 as well 216 as problems related to the introduction of artificial control cycles (Ruths & Ruths 2014); and third it 217 significantly reduces the computational resources necessary for the application of our approach (Supporting 218 Information S6). Moreover, we found that changing to unidirectional interactions based on the direction 219 of asymmetry does not alter the relative n_D of different networks (Table S3).

To find a maximum matching in a network with interaction directions and weights determined by the

asymmetry, we adopted a strategy based on an alternative bipartite representation of the directed network with two levels that indicate the outgoing and incoming links to each node (Supporting Information S1). Once we had this alternative representation we used the maximum bipartite matching algorithm implemented in the max_bipartite_match function of igraph 1.0.1 (Csardi & Nepusz 2006) on each network.

Statistical analysis

We also wanted to test whether invasion status or other predictors had an impact on the observed values of n_D . We therefore used a set of generalised linear models (with binomial error structure) to investigate the effect of invasion status while also including covariates related to species richness, since one might naively expect to see a negative relationship between richness and manageability (Menge 1995). These covariates included the total number of species, plant richness, pollinators richness, the ratio of plant to pollinator richness, the link density (connectance), and the study site (as a two-level factor).

We next explored whether real networks differ in their architecture from random ones in a concerted 233 way that affects manageability. Previous research indicates a direct link between a network's degree 234 distribution and the number of nodes necessary to fully control it (Liu et al. 2011), but the strength and 235 applicability of this relationship have not been tested for in weighted ecological networks. We therefore 236 compared the driver-node density n_D of the empirical networks to networks generated by a null model 237 that maintained each species' strength (its total sum of visits) while allowing their degrees (its number of 238 interactions) to vary. Beyond network structure, the dependence asymmetry plays a fundamental role in 230 determining the direction of control in each two-species interaction and therefore has the potential to 240 influence the network n_D results above. We therefore performed an additional randomisation in which we kept the structure of each network constant but randomised the direction of the interaction asymmetries. That is, we first calculated the observed asymmetries for each community and then shuffled the direction 243 of the link between each pair of species.

Additional details about the statistical models and the randomisations can be found in Supporting Information S7.

Relative importance

Our second key question was related to how species differ in their ability to drive the population dynamics of the community. To quantify this importance, we computed all maximal cardinality matchings in each network. We then calculated the frequency with which each species i was a driver (f_D) or a superior node (f_S) in the set of matchings that had a matching weight greater or equal to 0.8 times the

weight of the maximum matching. We selected this threshold as it provided a high agreement between
networks quantified by visitation and pollination efficiency as well as between our weighting/directionality
assumptions; however, the choice of this threshold had a negligible impact on any results (Supporting
Information S8). Details about the computational procedure to find all maximal cardinality matchings of
a network can be found in Supporting Information S1 and Figure S2.

Statistical analysis

We then examined whether any species-level structural properties could predict our metrics of species 256 importance—the frequency with which a species was a driver or a superior node (f_D and f_S , respectively). 257 We used a set of generalised linear mixed-effects models (with binomial error structure) with the relative 258 frequencies as the response variables. As predictors in this model, we included measures of centrality 259 (degree and eigen-centrality), which have been found to be strong predictors of importance in a coextinction 260 context (Memmott, Waser & Price 2004); a measure related to network robustness (contribution to 261 nestedness), as nestedness has been proposed as one of the key properties that promote stability in mutualistic networks (Saavedra et al. 2011); a measure of strength of association (visitation strength, the sum of visits a species receives or performs) and a measure of strength of dependence (species strength, 264 the sum of dependences of all species on the focal species), as their distribution determines the extent 265 of interspecific effects (Bascompte et al. 2006). In addition, we also included guild (plant or pollinator) 266 and whether the species is invasive or not as categorical fixed effects. Lastly, we allowed for variation 267 between different communities by including the network identity as a random effect (Bates et al. 2015). 268 Supplementary details about the statistical models can be found in Supporting Information S7.

Results

Manageability

All of the networks had a driver-node density n_D between 0.55 and 0.92 (mean 0.76; Figure 3a). In addition, we found that, when controlling for potential species richness effects, the n_D of invaded communities was smaller to those of non-invaded communities (Figure 3b). Nevertheless, of the various covariates we explored, the ratio of plants to pollinators showed the strongest relationship with n_D (Figure 3c; Table S5). Specifically as the proportion of pollinators increases and the ratio plant/pollinator approaches unity, n_D decreases (all our communities had more pollinators than plants). Other covariates—connectance (link density) and species richness—had negative, but comparatively less important, relationships with n_D .

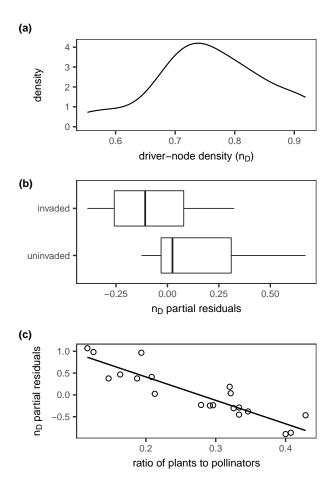

Figure 3: **Driver-node density**. (a) Histogram of the driver-node density (n_D) for the twenty networks. (b) Invaded communities have lower n_D than uninvaded communities even when controlling for factors related to species richness. The boxes cover the 25th–75th percentiles, the middle lines mark the median, and the maximum length of the whiskers is 1.5 times the interquartile range. (c) Out of the richness metrics, the ratio of plants to pollinators showed a strong, negative relationship with n_D . In both plots, partial residuals correspond to the partial working residuals of the invasion status in our generalised linear mixed model.

When exploring the effect of network structure itself, we observed that the driver-node density n_D of empirical networks was, in general, not significantly different to the manageability of network randomisations that maintained the degree of individual species (Figure 4). However, we found that the n_D of empirical networks was significantly larger than that of randomisations that maintained the network structure but that differed only in the direction of the asymmetries.

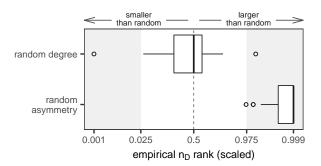

Figure 4: The driver-node density n_D of empirical networks compared to network randomisations. For each randomisation approach, we show the standarised rank of the empirical value compared to the set of randomisations. A scaled mean rank—akin to a p-value—less than 0.025 or greater than 0.975 (the areas shaded in light grey) suggests a significant difference between the empirical network and its randomisations. The empirical n_D is much larger than that of network randomisations in which the direction of asymmetries has been randomised. In contrast, the manageability of networks in which the species degrees were randomly shuffled were not significantly different. All boxes are as in Figure 3a.

Relative importance

Invasive species were classified as superior nodes and driver nodes in every single network they were present; that is, they always had the highest relative f_S and f_D (Figure 5a). The model results suggest that 283 these differences between invasive and native species are not underpinned by any intrinsic property of the invasive species; instead, they are due to species properties that apply to invasive and native species alike (Table 1). Specifically, we found that a species is more likely to be classified as a superior node if it had a large species strength (the sum of the dependences of all other species on the species of interest). To a 287 smaller extent, visitation strength (a species' sum of visits) and degree also had a positive relationship 288 with f_S . In contrast, the relationships between species structural properties and f_D were less clear cut 289 (Table 1). Both invasive species (which generally have a larger degree and high dependence strength) and 290 pollinators (which generally have a smaller degree and low dependence strength) were classified as driver 291 nodes in a large proportion of matchings. 292

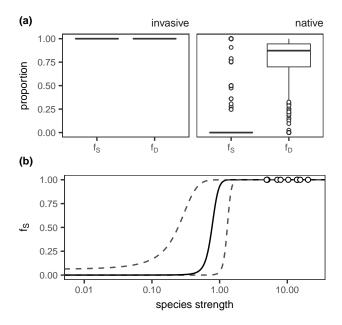

Figure 5: Relationships between f_S and f_D and species structural properties. (a) In all networks were they were present, invasive species were classified as superior (f_S) and driver (f_D) nodes in all possible control configurations. (b) Species strength (the sum of the dependences of other species on the species of interest) is the single most important factor explaining f_S . Visitation strength and degree also had an important albeit comparatively smaller effect (dashed lines correspond to \pm one standard deviation of these factors). Invasive species are depicted as circles.

Discussion

Contrary to our initial hypothesis, we found some evidence that invaded communities might be easier to 293 manage than uninvaded ones from a control-theoretic perspective. Our results reveal, however, that this 294 effect is comparatively small, and the structural differences among different networks are more strongly 295 related to potential differences in our ability to alter the state of the community via external interventions. Despite the small effect of invasion status at the network level, we found that invasive mutualists occupy a particularly dominant role in their communities for two reasons. First, as species with a high f_S , changes 298 on their abundance have the potential to propagate broadly through the community and, in turn, affect 299 the abundances of many other species. Second, as species with a high f_D , they are also indispensable 300 when it comes to fully controlling the plant-pollinator network. At a community level, we demonstrate 301 that the manageability of mutualistic networks is strongly governed by the asymmetric nature of mutual 302 dependences—which constitute the foundations of the structure and stability of mutualistic networks 303 (Memmott et al. 2004; Vázquez & Aizen 2004; Bascompte et al. 2006; Astegiano et al. 2015). Moreover, 304 these mutual dependences seem to be constrained by the effects of both the patterns of species richness 305 at each trophic guild and a network's degree distribution (Melián & Bascompte 2002; Blüthgen et al. 2007). Indeed, the difference between the driver-node density (n_D) of our empirical networks and that of randomisations depended strongly on the null model's randomisation approach. While the empirical n_D 308 was indistinguishable from that of networks with a random structure that maintained the degree of each

species in the community, it was larger than that of randomisations in which the directed network was unchanged but where the observed patterns of dependence were broken.

Invasive species have been previously found to exacerbate the asymmetries in their communities (Aizen et al. 2008; Bartomeus et al. 2008; Henriksson et al. 2016). Although this might cause differences both at the 313 community and the species level, we found that invasive plants are not inherently different to their native 314 counterparts (Stouffer, Cirtwill & Bascompte 2014; Emer et al. 2016). Invasive plants, just like any other 315 mutualist in our data set, tend to be classified as a superior node proportional to the degree to which 316 their interaction partners are collectively more dependent on them than the other way around. Previous 317 studies have found that supergeneralists, like invasive species, play a central role in their networks (Vilà et 318 al. 2009; Palacio, Valderrama-Ardila & Kattan 2016). Our results take this one step further and indicate 319 that dependence strength, rather than generalism or other metrics of centrality, is the factor that best 320 explains the cascading effects a species could trigger on its community.

Because of the ability that our approach has to infer the magnitude of the effects that each species has on others in the community, it is tantalising to use it to select promising candidates for management interventions. To this end, the two indices we have used to characterise a species provide two complementary pieces of information. Our first index f_D —the frequency with which a species is classified as a driver node—provides an indication of the likelihood that a species forms part of the set of species that must be manipulated in order to control *all* species in the community. This driver-node concept has received considerable attention in the structural-control literature and indeed shows substantial potential to provide useful ecological insight. Nevertheless, we anticipate two caveats that hinder its direct utility for management applications. First, unlike some other types of complex systems, fully controlling an ecological community is almost certainly out of reach for all but the simplest, due to either the number of required interventions or the practical difficulties of their implementation (Motter 2015). For instance, our results suggest that full control of the pollination networks would require direct interventions on anywhere from 40–90% of the species. Second, Ruths & Ruths (2014) established that driver nodes arise due to distinct mechanisms and therefore species with markedly different network metrics can act as driver nodes in their community (Supporting Information S2).

Our second index f_S , however, is directly related to the likelihood a species affects the abundance of 337 another species in all of the control strategies considered. Importantly, this is irrespective of whether 338 controlling the entire network is ultimately desired and/or feasible. In fact, because superior nodes are 339 always at the beginning of a matched link, species with a high f_S are more likely to be the subjects of 340 management interventions when controlling the abundances of a target set of species—as opposed to the 341 entire network—is desired (Gao et al. 2014). An important advantage here is that the target set of species does not have to be the same set to which interventions are applied. For instance, despite inconsistent outcomes in practice (Suding, Gross & Houseman 2004; Rodewald et al. 2015; Smith et al. 2016), our 344 results suggest that current restoration approaches that focus on direct eradication of invasive species might indeed be an effective way to modify ecosystem state. Nevertheless, our results also indicate that 346 removals must be exercised with caution. Not only it is hard to predict the direction in which the system 347 will change, but invaded communities also tend to be highly dependent on invaders and therefore acutely 348 vulnerable to their eradication (Traveset et al. 2013; Albrecht et al. 2014).

Despite the apparent similarities, our approach is different to previous attempts to quantify species importance in a few key ways. Existing metrics usually harness species features, like centrality, position, co-extinction or uniqueness, to infer their effect on other species (Allesina & Bodini 2004; Jordán, Liu & Davis 2006; Jordán 2009; Lai, Liu & Jordan 2012). In contrast, our control-based approach tackles that 353 question directly. Although they are relatively simple to calculate, classic species-level network metrics do 354 not necessarily reveal the best set of species to manage (Eklöf, Tang & Allesina 2013; McDonald-Madden 355 et al. 2016). Our approach, however, is not based on a single structural metric but instead acknowledges 356 the existence of multiple management strategies. By allowing for the fact that some strategies are better 357 than others depending on the context, control theory implicitly highlights that management decisions 358 should not be based on a single technique. As such, ours and other flexible approaches that take a 359 network-wide approach might prove more useful to guide ecosystem management (McDonald-Madden et al. 2016).

In this study, we illustrate how a control-theoretic approach can be employed in network ecology to evaluate the effect of invasions and other kinds of perturbations. We study the different ways a management

intervention can be structured and provide a starting point for the continued study of controllability in 364 ecological contexts. Although our pollination-specific results might not be directly translatable to other 365 ecological networks that do not have bipartite structures, the approach we propose is applicable wherever species abundances are influenced by their interactions, and exciting open questions lie ahead. How to design the precise "control signals" to reach a desired ecosystem state or conservation outcome? What are the implications of assuming fully nonlinear dynamics? How important it is to include several interaction 369 types for our understanding of manageability and species importance? What are the implications for 370 species coexistence? Which are the trade-offs between persistence at the species and the community 371 level? Answering each of these questions might require its evaluation in different ecological systems, an 372 explicit integration of control theory with numerical models of species densities (Cornelius et al. 2013; 373 Gibson et al. 2016), and experimental tests on simple communities. Nevertheless, the potential rewards 374 are encouraging from both an ecological and conservation perspective, where an integrated approach 375 can shift the focus beyond the identification of ideal targets for intervention to the design of informed interventions that legitimately achieve restoration goals.

Appendix 1: Glossary

- Driver node An unmatched node in a maximal cardinality matching or a maximum matching. From
 the control perspective, driver nodes are those to which external control signals must be applied in
 order to gain full control of the network.
- Matched/unmatched link A link is referred to as matched if it is part of a matching, and unmatched otherwise.
- Matched/unmatched node A node is referred to as matched if it is at the end of a matched link, and
 unmatched otherwise.
- Matching A set of links in which no two of them share a common starting or ending node.
- 386 Matching size The number of matched links in a matching.
- Matching weight The sum of the weights of all matched links in a matching.
- Maximal cardinality matching A matching with the largest possible matching size. In unweighted/binary networks, all maximal cardinality matchings are also maximum matchings.
- Maximum matching A matching with the largest possible matching size and largest possible matching weight.
- Superior node The node at the start of a matched link. From the control perspective, superior nodes
 make up the chains that propagate the control signals through the network.

Acknowledgments

- The authors thank Jane Memmott and coauthors, and eveyone that has made their data available to
- us, Takeuki Uno for the insight provided to find the set of all maximum matching algorithms, and
- Jason Tylianakis, Bernat Bramon Mora, Guadalupe Peralta, Rogini Runghen, Warwick Allen, Matthew
- Hutchinson, and Marilia Gaiarsa for feedback and valuable discussions. EFC acknowledges the support
- from the University of Canterbury Doctoral Scholarship, the University of Canterbury Meadow Mushrooms
- Postgraduate Scholarship, a New Zealand International Doctoral Research Scholarship, and a travel grant
- 400 from the European Space Agency. DBS acknowledges the support of a Marsden Fast-Start grant and a
- 401 Rutherford Discovery Fellowship, administered by the Royal Society Te Aparangi.

Author contributions

- DBS conceived the idea; all authors contributed to the development of the theoretical framework. EFC
- performed all analysis. EFC and DBS wrote the manuscript. All authors contributed to its revision.

Data accessibility

- All data used in this manuscript have already been published by Lopezaraiza-Mikel et al. (2007), Bartomeus
- et al. (2008), and Ballantyne et al. (2015). The reader should refer to the original sources to access the
- 406 data.
